

# SGX Project

Team Awesome

August 2, 2016

### **Abstract**

Web Servers are now often deployed in the cloud environment. To secure communications in the middle of the network between clients and web servers, the Internet community has come to rely on the SSL/TLS protocol which requires a strong secret (private key) to be stored with the server. However, the server administrator, in this model, is forced to trust the cloud provider to not disclose their private key. We propose a modification to legacy web servers and cryptographic libraries which secures the sensitive key material in the face a malicious provider or a compromised operating system without the need to trust the cloud provider and/or operating system.

# 1 Introduction

With the recent surge in privacy concerns, employing SSL/TLS to secure communications in the middle of the network has become common place. SSL/TLS offers guarantees of confidentiality and integrity provided that a private key's secrecy is maintained. Yet, SSL/TLS was designed assuming that its user trusts the hardware and OS of the machine on which the key is held.

While this assumption is perfectly valid in the case where a person is running an SSL/TLS enabled service on their own machines, many web applications are now hosted by third party cloud service providers such as Amazon Web Services, Heroku, Digital Ocean &c. Moreover, to offer SSL/TLS, the private key must also be stored with the web application on these service providers' machines. This implies that a server administrator using the aforementioned services is trusting the cloud-provider, including any personnel with physical/administrative access to the machines, and the underlying OS to maintain the secrecy of the sensitive key material. Such a wide trust surface makes it difficult to maintain the privacy of critical secrets.

Consider a case where the cloud provider is not malicious; a vulnerability within their platform could lead to leaking the private key if exploited by an adversary. Moreover, if the cloud provider is indeed malicious they could simply read your private key from the hard disk if stored unencrypted, or mount some form of memory sniffing attack to read the key from the web server's memory since data in RAM is unencrypted. A compromised private key allows an adversary to do the following:

- Decrypt past, stored, communication between the web server and a client (assuming a cipher that does not provide perfect forward secrecy is in use)
- Decrypt any ongoing communication between the web server and a client
- Masquerade as the server and fool a client into disclosing sensitive information such as passwords

In all cases, a compromised key voids the confidentiality and integrity guarantees of SSL/TLS.

The goal of this project is to secure the private key in the face of:

1. An adversary who exploits the server application
2. A malicious cloud provider
3. An adversary with an exploit for the underlying operating system

The first point has been extensively addressed in previous works including Wedge and OKWS; the latter two have been discussed in recent works such as Haven.

## 2 Background

### 2.1 An overview of Intel SGX

This section will not cover all of the details of SGX but only those applicable to our project, for a complete treatment of SGX please refer to [PLACEHOLDER]. Intel SGX is a set of x86 instructions that allow for a programming model wherein a program can be split into two components: an untrusted component that executes as normal and a trusted component that executes within a protected area of RAM, called an enclave, which can only be accessed when executing the trusted component.

The protection of an enclave is managed by the CPU; any data written to the enclave is encrypted first by a memory encryption engine (implemented in hardware) and is only decrypted when required by the CPU during the execution of the trusted component for which that enclave belongs. The key used for this encryption process is derived from a combination of a device key, unique to each SGX-enabled CPU and the “identity” of the enclave called MRENCLAVE, a cryptographic hash of the enclave’s contents at the trusted component’s initialization. SGX thus ensures that no process other than the one that initialized the enclave can access the protected area.

Interacting with the trusted component, as a result, may only occur through invoking a programmer defined interface, called a callgate, as depicted in Figure 1.

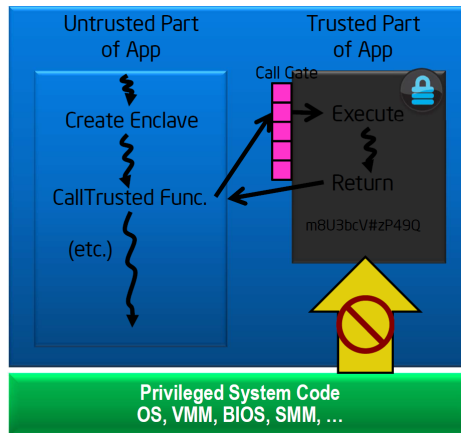

Figure 1: Interaction of the untrusted part of the application with the trusted part can only occur through a callgate

### 2.2 Provisioning the enclave with the long-term private key

Provisioning a web server with a long-term private key for the purposes of SSL/TLS is currently done storing the private-key along with the executable on

the remote machine. This scheme, however, assumes a trusted cloud-provider/OS. However, under our threat model this scheme is not viable. Alternatively, we require a method by which we can verify the identity and integrity of the server application and then, upon successful verification, we can send the long term private key to the server in a secure fashion. Loosely, the requirements are as follows:

- The mechanism allows the verification of the identity and integrity of the server application and the underlying TCB. This is so that we can be sure the private-key is being sent to the same server we placed on the remote machine, and the software is being executed by trustworthy hardware.
- The mechanism allows us to setup a secure channel, ensuring that the only entities privy to the private key are the server application and the server administrator.

The first and second requirement are met by a process called inter-platform attestation.

## 2.3 Inter-platform attestation

Inter-platform attestation is a mechanism that can be invoked by an entity, referred to as the challenger, running on one platform to verify an enclave running on another, remote, platform. This process enables the challenger to verify the following about the remote enclave:

1. The contents of the enclave's pages (code, data, stack and heap) upon creation (after the ECREATE instruction completes)
2. The identity of the entity that signed the enclave
3. The trustworthiness of the underlying hardware
4. Authenticity and integrity of any data generated by the enclave and sent as part of the attestation process. This allows us to satisfy the second requirement by generating an ephemeral key pair and binding it to the remote attestation process. This, therefore, allows the challenger to verify the integrity of the ephemeral public key and verify that it was generated by the server application.

The steps involved in the attestation process are as follows (illustrated in Figure 2):

1. The challenger invokes the remote attestation mechanism to verify the identity and integrity of the remote enclave
2. The non-trusted part of the web server receives the challenge, passes it along to the trusted portion of the web server along with the identity of the quoting enclave. The quoting enclave is a special enclave provided by Intel as part of the SGX platform to enable remote attestation by verifying the integrity of the underlying hardware.

3. The enclave invokes EREPORT which is an SGX instruction that generates a REPORT structure to be provided to a *local* enclave, the quoting enclave in this case. This structure contains a hash of the contents of the enclave's pages upon ECREATE's termination, a hash of the identity of the enclave's signer, a hash of any user-data, the ephemeral key in our case, generated by the enclave. The REPORT is signed by a MAC-key that can only be accessed by the CPU and the quoting enclave. The REPORT along with the ephemeral key is then sent to the non-trusted part of the application.
4. The REPORT is sent to the quoting enclave where its integrity is verified by calculating the MAC across its contents.
5. Assuming the REPORT is verified successfully, the quoting enclave generates a QUOTE structure that includes the REPORT structure and a signature across the quote generated using a key known as the EPID key. The EPID key is a private key unique to the CPU that is part of the platform and verifies the firmware of the processor and its SGX capabilities.
6. The QUOTE is sent along with the ephemeral key to the challenger
7. The challenger verifies the QUOTE structure by using an EPID public certificate. If this is successful then the challenger is sure that this QUOTE came from a valid SGX CPU and can trust its authenticity. The challenger can then check the contents of the REPORT contained within the QUOTE to verify the identity of the remote enclave, and the integrity of the ephemeral key received along with the QUOTE. The ephemeral key, if proven to be valid, can now be used to communicate with the remote enclave in a secure manner.

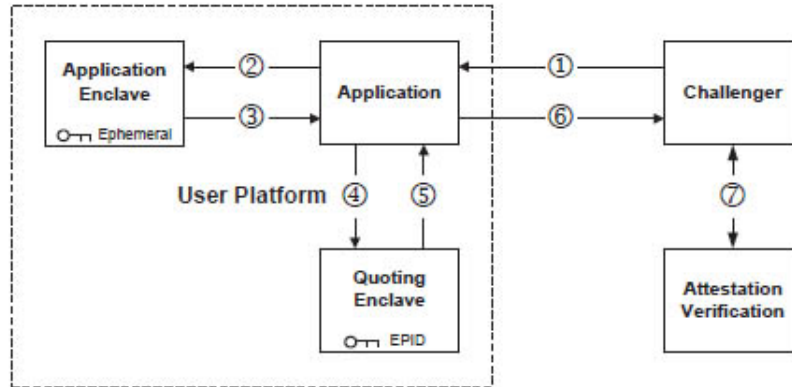

Figure 2: Remote Attestation and Secret Provisioning

### 3 Design

By utilizing the aforementioned remote-attestation process, we can provision the trusted component of the remote server application with an SSL private key while making it extremely difficult\* for even *privileged* processes running on the cloud provider to access the key. This is a stark contrast to current schemes wherein the private key is merely shipped as part of the server application to the cloud provider.

In SSL/TLS, the private key is required by some operations during the handshake step to derive an ephemeral symmetric session key. These operations are executed within the trusted component, and are invoked by the non-trusted component via an interface that we define in this section. Note that the interface has to be carefully designed to allow the handshake to complete correctly while not exposing the long term private key through an oracle. However, before discussing the design we have implemented, we first provide a brief overview of the SSL/TLS handshake, highlighting the steps where the private key is used.

#### 3.1 SSL/TLS handshake

To generate the master key, from which further (session) keys are derived, the RSA handshake requires three random components:

- Client random - generated by the client and sent over the network in the clear
- Premaster secret - generated by the client and sent, encrypted with the server's public key, over the network
- Server random - generated by the server and sent in the clear

The secrecy of the master key is guaranteed by the fact that only the server is in possession of the private key to decrypt the premaster secret.

We need to secure against the malicious OS supplying the server random component, which would force the trusted component to generate the same session keys which would lead to private key oracle. [Wedge citation]

We consider two scenarios:

- Session keys available to the OS
- Session keys hidden inside the enclave and accessible through encrypt/decrypt oracle
